Abstract

We consider a variant of the stochastic multi-armed bandit problem where arms are known to be organized into different groups having the same mean. The groups are unknown but a lower bound $q$ on their size is known. This situation typically appears when each arm can be described with a list of categorical attributes, and the (unknown) mean reward function only depends on a subset of them, the others being redundant. In this case, $q$ is linked naturally to the number of attributes considered redundant, and the number of categories of each attribute. For this structured problem of practical relevance, we first derive the asymptotic regret lower bound and corresponding constrained optimization problem. They reveal the achievable regret can be substantially reduced when compared to the unstructured setup, possibly by a factor $q$. However, solving exactly the exact constrained optimization problem involves a combinatorial problem. We introduce a lower-bound inspired strategy involving a computationally efficient relaxation that is based on a sorting mechanism. We further prove it achieves a lower bound close to the optimal one up to a controlled factor, and achieves an asymptotic regret $q$ times smaller than the unstructured one. We believe this shows it is a valuable strategy for the practitioner. Last, we illustrate the performance of the considered strategy on numerical experiments involving a large number of arms.

1 Introduction

The finite stochastic multi-armed bandit problem is a popular framework for studying sequential decision making problems in which a learner sequentially samples from a finite set of distributions called arms. It was first introduced in the context of medical trials [Thompson, 1933b, 1935] and later formalized under this name by Robbins in Robbins [1952]. We refer the interested reader to Lattimore and Szepesvári [2020] for a recent survey. This is one of the simplest theoretical framework in which one can study the notion of exploration-exploitation tradeoff. This tension between exploration and exploitation arises from the sequential optimization problem a learner is trying to perform while being uncertain about the very problem it is optimizing.

Formally, a multi-armed bandit configuration is specified by a set of unknown real-valued probability distributions $\nu = (\nu_a)_{a \in A}$ with means $(\mu_a)_{a \in A}$, indexed by a set of arms $A$. We hereafter consider a finite $A$, and that all $\nu_a$, $a \in A$ belong to the same family of distributions $\mathcal{F}$ (e.g. Bernoulli, Gaussian, etc.), that is $\nu \in \mathcal{F}^A$. The bandit game proceeds as follows. At each time $t \in \mathbb{N}$, the learner chooses an arm $a_t \in A$ based on the past observations and decisions, then receives and observes a sample $X_t$ (called the reward), conditionally independent, sampled from $\nu_{a_t}$. Her goal is to maximize the cumulative reward received over time. The mean of each arm is unknown, which makes the problem non-trivial, hence the learner should adjust her sampling strategy based on past information obtained from drawing different arms in order to maximize the expected sum of rewards. The maximal expected value of a finite bandit configuration is denoted by $\mu_*$, defined as $\mu_* = \max_{a \in A} \mu_a$. The performance of the strategy used by the agent is measured by the (pseudo) regret, that compares the
expected sum of rewards obtained by an oracle that would constantly pull an optimal arm and the ones obtained by the learner, up to some time horizon $T$ (that we assume is unknown to the learner).

**Definition 1 (Regret).** The regret incurred by a sampling strategy after $T$ time steps on a bandit configuration $\nu$ is given by:

$$R(\nu, T) = \mathbb{E}_\nu \left( \sum_{t=1}^{T} (\mu_a - \mu_a) \right) = \sum_{a \in A} (\mu_a - \mu_a) \mathbb{E}_\nu \left( N_a(T) \right),$$

where $N_a(T) = \sum_{t=1}^{T} \mathbb{I}(a_t = a)$ denotes the number of selection of arm $a$ after $T$ time steps.

**Group of similar arms** Motivated by various practical reasons, one may want to restrict to a subset $B \subseteq A$ of allowed bandit configurations instead of the full set $A$. In this paper, we study a variant of the multi-armed bandit problem in which the reward function, $\mu : a \in A \rightarrow \mu_a$, is assumed to satisfy a cluster-like structural property. A bandit configuration $\nu$ is said to satisfy the $q$-equivalence property if for every arm $a \in A$, there are at least $q-1$ distinct arms having the same expected value:

$$\forall a \in A, \quad |\{a' \in A | \mu_a' = \mu_a\}| \geq q.$$

Assuming the set of arms $A$ and base distributions $D$ are known to the learner, we denote by $B_q$ the set of bandit configurations having the $q$-equivalence property. We also denote by $B_q(\mu)$ the set of all expected values in $B_q$. Formally, $B_q(\mu)$ is the image of $B_q$ under the $\mu$ mapping.

**Definition 2 (Arm equivalence and equivalence class).** Given a bandit configuration $\nu$, two arms $a, a' \in A$ are said to be equivalent if their associated distributions have the same expected values:

$$a \sim a' \Leftrightarrow \mu_a = \mu_a'.$$

An equivalence class $c$ in $\nu$ is a maximal subset of arms in $A$ having the same mean, i.e., for all arms $a, a' \in c$, $\mu_a = \mu_a'$ and for all arm $a \in c$ and $a' \in A \setminus c$, $\mu_a \neq \mu_a'$.

This situation typically appears in practical situations when each arm can be described with a list of categorical attributes, and the (unknown) mean reward function only depends on a subset of them, the others being redundant. In this case, $q$ is naturally linked to the number of attributes considered redundant (or useless descriptors), and the number of categories of each attribute. Precisely, $q = \prod_{i \in \mathcal{R}} c_i$ where $\mathcal{R}$ is the set of redundant attributes and $c_i$ the number of categories for attribute $i$. The learner may know that there exists such a structure while not knowing a closed form formula mapping the list of categorical attributes to the significant subset. In this case, $q$ might be a lower bound on the sizes of the class since the set $R$ might not be the largest possible one or because the number of redundant attributes depends on the number of relevant attributes. In all cases, the smallest possible number of redundant attributes can be naturally linked to $q$. We hereafter consider the learner only knows $q$ but would like to exploit the prior knowledge of this structure in a bandit problem.

**Regret lower bounds overview** In order to assess the performance of a bandit algorithm on a set of configurations $B$, one naturally studies the best guarantee achievable by a uniformly efficient algorithm on $B$, i.e. with sub-linear regret on any instance $\nu \in B$ of the bandit problem. When $B = \mathcal{F}^A$, such a guarantee was first provided by [Lai and Robbins, 1985] for parametric families $\mathcal{F}$, and then extended by [Burnetas and Katehakis, 1996] for more general families. It states that any algorithm that is uniformly efficient on a family of distributions $\mathcal{F}$ must satisfy

$$\liminf_{T \to \infty} \frac{R(\nu, T)}{\log(T)} \geq \sum_{a : \mu_a > \mu} \frac{\mu_a - \mu_a}{K_{\mathcal{F}}(\nu_a \| \mu^*)}, \quad K_{\mathcal{F}}(\nu_a \| \mu^*) = \inf_{G \in \mathcal{F}} \{\text{KL}(\nu_a \| G) : E_G(X) > \mu^*\}. \quad (1)$$

This popular result entails that any strategy having the desirable property to have sub-linear regret on any instance of $\mathcal{F}$ must incur a non-trivial minimal regret. When $B$ is a strict subset of $\mathcal{F}^A$, the bandit problem is called structured, as in this case pulling an arm may reveal information that makes it possible to refine estimation of other arms (e.g. think of the set of bandit configurations having Lipschitz mean function with respect to $A \subseteq \mathbb{R}^d$). The presence of structure may considerably modify the achievable lowest regret, as shown in [Burnetas and Katehakis, 1996] and [Graves and Lai].

\textsuperscript{1}Formally, for each bandit on $\mathcal{F}$, for each arm $k$ with $\Delta_k > 0$, then $E[N_k(T)] = o(T^\alpha)$ for all $\alpha \in (0, 1)$.
who extended the (unstructured) lower bounds to arbitrarily structured bandit problems (and beyond). These lower bound take the generic form \( \liminf_{T \to \infty} \frac{R(\nu, T)}{\log(T)} \geq \mathcal{C}_B(\nu) \), where \( \mathcal{C}_B(\nu) \) is a constant term solution of a constrained linear-optimization problem. A bandit algorithm is then called asymptotically optimal for a set \( B \) when its regret asymptotically matches this lower bound.

**Existing strategies** In order to minimize the regret, a learner faces the classical exploration/exploration dilemma: it needs to balance exploration, that is gaining information about the expected values of the arms by sampling them, and exploitation, that is playing the most promising arm sufficiently often. Many algorithms have been proposed to solve the multi-armed bandits problem (see [Lattimore and Szepesvári 2020] for a survey). The study of the lower bounds had a crucial impact on the development of provably asymptotically optimal strategies. In the case of unstructured bandit \( B = \mathcal{F}^A \), this includes strategies that build on the concept of Optimism in Face of Uncertainty (the most celebrated of which being the Upper Confidence Bound (UCB) algorithms [Agrawal 1995], [Auer et al. 2002]), such as KLUCB [Lai 1987, Cappé et al. 2013, Maillard 2018], UMED and TED [Honda and Takemura 2011, 2015], that are proven asymptotically optimal for various families \( \mathcal{F} \) (e.g. one-dimensional exponential families), and directly exploit the lower bound in their structure. Alternative asymptotically optimal strategies include the Thompson Sampling (TS) [Thompson 1933a, Agrawal and Goyal 2012], which uses a Bayesian posterior distribution given a specific prior, whose optimality was shown in [Korda et al. 2013]. See also [Kveton et al. 2019] for other randomized algorithms and [Kveton et al. 2020, Chan 2020, Baudry et al. 2020] for recent non-parametric extensions using re-sampling methods. Further, some authors also allow many optimal arms, see [de Heide et al. 2021], or even countably many arms, see [Kalvit and Zečević 2020]. However, these works do not consider nor exploit a constraint on the level-sets of the mean function and follow an optimistic paradigm while we follow an information minimization targeting optimality.

On the other hand, several instances of structured bandits received considerable attention in the last few years. This is the case for instance of linear bandits, see [Abbasi-Yadkori et al. 2011, Srinivas et al. 2010, Durand et al. 2017, Kveton et al. 2020] and [Lattimore and Szepesvári 2017]. Lipschitz bandits [Magureanu et al. 2014, Wang et al. 2020, Lu et al. 2019], unimodal bandits [Yu and Mannor 2011], Combes and Proutière [2014], Saber et al. 2020, or combinatorial bandits [Kveton et al. 2015, Magureanu 2018], and more recently [Cuvelier et al. 2021b]. A generic asymptotically optimal algorithm, called OSSB (Optimal Structured Stochastic Bandit), has been introduced in the work of [Combes et al. 2017], and proven to be asymptotically optimal for all structures satisfying some weak properties that include all the aforementioned structures. Although being asymptotically optimal this algorithm often suffers from a long burn-in phase that may hinder its finite practical performance. It further comes with high computational price as it requires to solve an empirical version of the optimization problem \( \mathcal{C}_B(\nu) \) at each step. This motivates the quest for alternative strategies, perhaps less generic but better suited to a specific structure. Inspired by combinatorial structures for which computing \( \mathcal{C}_D(\nu) \) is simply not feasible, a relaxation of the generic constrained optimization problem was recently proposed in [Cuvelier et al. 2021a]. The authors show that this comes at the price of trading-off regret optimality for computational efficiency. Indeed in some structure, combinatorial properties are at stake and asymptotically optimal algorithms may require solving combinatorial optimization problems (see [Cuvelier et al. 2021a]) related to \( \mathcal{C}_B(\nu) \). In order to exploit the combinatorial structures in a numerically efficient way, research has been made in how to relax these combinatorial optimization problems while preserving theoretical properties on the regret of the relaxed algorithms (see [Cuvelier et al. 2021b]). Our work consider similar computational issues, with a different perspective.

**Goal** For the structure \( B_{\nu} \), as we show in Theorem 1 below, the term \( \mathcal{C}_{B_{\nu}}(\nu) \) unfortunately makes appear in general a combinatorial optimization problem. This makes resorting to OSSB or any strategy targeting exact asymptotic optimality a daunting task for the practitioner. In this paper, our goal is to provide a computationally efficient strategy adapted to the structure \( B_{\nu} \), that is able to reach optimality up to controlled error term.

**Outline and contributions** The rest of this paper is organized as follows. In section 2, we derive a lower bound on the regret for the structured set of bandit configurations \( B_{\nu} \). This bound makes appear two components, one that we call non-combinatorial as optimizing it can be done efficiently, and a second term that we term combinatorial as it involves solving a combinatorial problem. Interestingly, using in Lemma 1 and Theorem 2 that the contribution of the combinatorial part of the lower bound
When $\lambda > \mu$

At each time step, the complexity of computing the next arm to be pulled by IMED-EC, an adaptation of the IMED strategy from Honda and Takemura [2015] to the structured set $B_q$. One advantage of IMED over a KL-UCB alternative is its reduced complexity, which translates to the equivalence class setup. At each time step, the complexity of computing the next arm to be pulled by IMED-EC is no more than the one of sorting a list of $|\mathcal{A}|$ elements once the IMED indexes have been computed, which is only $\log |\mathcal{A}|$ times larger than looking for the minimal IMED index. In Section 4, we prove that IMED-EC achieves a controlled asymmetric regret that matches the non-combinatorial part of the lower bound and is at most (less than) a factor of 2 times the optimal regret bound. Last, we illustrate the benefit of the IMED-EC over its unstructured version in Section 5, where it shows a substantial improvement. Our experiments also highlights the robustness of the algorithm to a misspecified parameter $q$, which is a desirable feature for the practitioner.

## 2 A regret lower bound with combinatorial and non-combinatorial parts

In this section, we derive a lower bound on the number of pulls of suboptimal arms that involves a combinatorial optimization problem. Using that lower bound, we derive a simple algorithm, IMED-EC, that does not involve any optimization problem. While not being asymptotically optimal, we will show in the next section that our algorithm has an upper bound on its regret that is no more than a fraction of the unstructured regret.

The proof of Theorem 1 is based on the concept of **most confusing instance**. Most confusing instances allow to assess the intrinsic difficulty of a bandit problem and allow to compute lower bounds on the number of times suboptimal arms are pulled. The lower bound informs us on the minimal amount of exploration one needs to do to solve a bandit problem. More formally, a confusing instance $\nu'$ associated to a suboptimal arm $a$ for a bandit problem $\nu$ is a bandit instance with the same set of arms as the original one, but in which $\mu_a$ has been changed to $\mu'_a > \mu_a$. An optimal sampling strategy (one that does not sample suboptimal arms too much) should behave differently on the two problems. Studying this difference, we can compute the minimal amount of exploration performed by an optimal strategy on arm $a$ in the original problem $\nu$. Doing so for all suboptimal arms allows to bound the number of samples of suboptimal arms and therefore characterize the intrinsic complexity of a bandit instance $\nu$.

In a structured setting, a confusing instance also has to respect the structure. In our case, it means that a confusing instance cannot have a class with less than $q$ arms. We will therefore consider confusing instances associated to classes rather than individual arms.

**Definition 3 (Confusing instance).** Given a bandit configuration $\nu \in B_q$, a real number $\lambda$ and a subset $c_q \subseteq \mathcal{A}$ of $q$ equivalent arms in $\nu$, we denote by $B_q(\nu, c_q, \lambda)$ the set of all bandit configurations having the same set of arms as $\nu$ and such that for all $\nu' \in B_q(\nu, c_q, \lambda)$, $\nu' \in B_q$ and for every arm $a$ in $c_q$, $\mu'_a \geq \lambda$.

When $\lambda > \mu_a$, and $c_q$ is a subset of a suboptimal class, a bandit configuration in $B_q(\nu, c_q, \lambda)$ is called a **confusing instance** of $\nu$.

Similarly to the notation introduced above, we will use the notation $B_q(\mu, c_q, \lambda)$ to specify the set of means of bandit configurations in $B_q(\mu, c_q, \lambda)$.

The aim of an asymptotic lower bound on the number of pulls of a suboptimal arm is to mathematically understand the minimal asymptotic amount of exploration an algorithm should perform.

**Assumption 1:** The family $\mathcal{F}$ is such that for all $\kappa \in \mathcal{F}$, $\mu \mapsto K_{\mathcal{F}}(\kappa \| \mu)$ and $\mu \mapsto K_{eq}(\kappa \| \mu)$ are continuous, where $K_{eq}(\kappa, \mu) = \inf_{G \in \mathcal{F}} \{ KL(\kappa, G) : E_G(X) = \mu \}$ with KL being a notation for the relative entropy or Kullback-Leibler divergence.

**Assumption 2:** The family $\mathcal{F}$ is an exponential family of dimension 1. Therefore the KL divergences are parameterized by the mean and we may write the KL as a function of the means, $\forall \kappa, \chi \in \mathcal{F}, KL(\kappa \| \chi) = KL(E_{X \sim \kappa}(X) \| E_{X \sim \chi}(X))$ (identification of the KL with its parameterization by the means).

**Theorem 1 (Asymptotic lower bound).** Let $q \in \mathbb{N}$ be a positive integer and $\nu \in B_q$ be a bandit configuration having the $q$-equivalence property. Let $c \subset \mathcal{A}$ be a suboptimal equivalence class in $\nu$. 

4
Assuming uniform consistency, for all suboptimal arms $a$,

$$\forall \alpha > 0, \lim_{T \to +\infty} \mathbb{E} \left( \frac{N_a(T)}{T^\alpha} \right) = 0,$$

assuming assumption 1, we have the following asymptotic bandit dependent lower bound on the number of pulls of arms in $c$:

$$\liminf_{T \to \infty} \frac{\min_{\nu \in C} \sum_{a \in c} \mathbb{E}_\nu (N_a(T)) K_{\mathcal{F}} (\nu_a || \mu_s) + \inf_{\nu' \in \mathcal{B}_q(\mu, \epsilon, \mu_s)} \sum_{a \notin c} \mathbb{E}_\nu (N_a(T)) K_{eq}(\nu_a || \mu'_a)}{\log T} \geq 1,$$

(2)

where $c_q$ is any subset of $c$ having $q$ distinct arms within it.

We briefly sketch how confusing instances are used in the proof of Theorem 1. We consider confusing instances in which $q$ arms from a suboptimal class $c$ are moved above the optimal one (w.r.t. the mean). If there are $q$ arms in the class, then there are no remaining arms to move. If there are more than $2q$ arms, then moving $q$ arms creates a reminder of size larger than $q$ meaning that the crafted confusing instance respects the equivalence structure. However, if there are between $q + 1$ and $2q - 1$ arms, then the reminder is of size larger than 1 but strictly smaller than $q$. The created confusing instance does not respect the equivalence structure and we have to deal with the arms in the reminder (the infimum of equation (2)). There are $|c|$ choose $q$ possible choices to move $q$ arms from class $c$ (the minimum of equation (2)). All in all, the lower bound involves a combinatorial optimization problem.

While this lower bound involves a combinatorial optimization term, one can distinguish between two regimes depending on the size of the suboptimal class. The combinatorial regime and the non-combinatorial regime.

**Non-combinatorial regime** For a suboptimal class $c$, if $|c| = q$ or $|c| \geq 2q$, then the lower bound reduces to

$$\liminf_{T \to \infty} \frac{\min_{\nu \in C} \sum_{a \in c} \mathbb{E}_\nu (N_a(T)) K_{\mathcal{F}} (\nu_a || \mu_s)}{\log T} \geq 1,$$

because the reminder is of size larger than $q$ and the infimum from Theorem 1 disappears. Indeed, the infimum is always 0 as this quantity can be obtained by choosing $\mu'_a = \mu_a$ for all $a \in c \setminus c_q$. Furthermore, the minimum over all $q$-partitions of $c$ is in fact the sum of the $q$ smallest elements of $\{ \mathbb{E}_\nu (N_a(T)) K_{\mathcal{F}} (\nu_a || \mu_s) \}_{a \in c}$. The search amongst all the $q$-partitions of $c$ amounts to a research of the $q$ smallest elements which is not more complex than sorting a list of $|c|$ elements. Hence, the problem is no more a combinatorial optimization one and we call this case the non-combinatorial regime.

**Lemma 1.** Let $\nu \in \mathcal{B}_q$ be a bandit configuration having the $q$-equivalence property. Let $c$ be a suboptimal class in the non-combinatorial regime, then, under assumption 1 and 2,

$$\liminf_{T \to \infty} \frac{\sum_{a \in c} \mathbb{E}_\nu (N_a(T))}{\log T} \geq \frac{|c|}{q} \frac{1}{K_{\mathcal{F}} (\nu || \lambda)}.$$

(3)

While we do not have information about individual number of times an arm in a class has been sampled, Lemma 1 roughly tells us than on average, the lower bound on the minimal amount of exploration of an arm in a suboptimal class has been divided by $q$.

**Lemma 2.** If all suboptimal classes are in the non-combinatorial regime, under assumption 1 and 2, the regret may be asymptotically lower bounded by

$$\liminf_{T \to \infty} \frac{R(\nu, T)}{\log T} \geq \frac{1}{q} \sum_{a \in A \setminus A_s} \frac{\mu_s - \mu_a}{K_{\mathcal{F}} (\nu_a || \lambda)}.$$

(4)

Lemma 2 informs us that in the non-combinatorial regime, the classical lower bound on the regret given by equation (1) has been divided by $q$. 

5
Combinatorial regime For a suboptimal class \(c\) to be in the combinatorial regime, we need \(q < |c| < 2q\) since the reminder is such that \(0 < |c \setminus c_q| < q\) and the infimum in Theorem\(1\) is not 0. In that case, the lower bound \(2\) involves a combinatorial optimization problem. Two difficulties arise from the term
\[
\inf_{\mu' \in B_q(\mu, c_q, \lambda)} \sum_{a \notin c_q} \mathbb{E}_{\nu} \left( N_a(t) \right) K_{eq} \left( \nu_a \| \mu'_a \right).
\]
First, while we could have thought that summing on the reminder \(c \setminus c_q\) would be enough, the summand has to be on \(a \notin c_q\) as a whole. Indeed, the residual \(c \setminus c_q\) may be of size \(q - 1\) meaning that it might cost less to move an arm from another class to the residual in order to complete it rather than moving all the reminder. Second, while we could have thought that moving elements from one class of \(\nu\) to another might be enough, the infimum has to be taken on \(B_q(\mu, c_q, \lambda)\). Indeed, the residual \(c \setminus c_q\) may be of size \(q - 1\) and the nearest class might be of size exactly \(q\). In this case, it may cost less to move all the \(2q - 1\) distributions in between the two classes and create a new one rather than merging one of the two with the other.

**Lemma 3.** Let \(\nu \in B_q\) be a bandit configuration having the \(q\)-equivalence property and \(c\) be a suboptimal class in the combinatorial regime. Then, under assumptions 1 and 2,
\[
\lim_{T \to \infty} \frac{1}{\log T} \sum_{a \in c} \mathbb{E}_{\nu} \left( N_a(t) \right) \geq \frac{1}{|c|} K_F \left( \nu_a \| \mu_\ast \right) + \frac{|d - q|}{|c|} \min_{\kappa \in F} K_{eq} \left( \nu_a \| \kappa \right),
\]
(5)
\[
\lim_{T \to \infty} \frac{1}{\log T} \sum_{a \in c} \mathbb{E}_{\nu} \left( N_a(t) \right) \geq \frac{1}{2q} \sum_{a \in c} K_F \left( \nu_a \| \mu_\ast \right).
\]
(6)

Those equations can be compared to the equation \(3\) from the non-combinatorial regime. We emphasize the fact that the lower bounds given by equations \(5\) and \(6\) are not the largest possible lower bound and hence do not provide as much information about the algorithmically achievable regret as the largest one given by equation \(2\). However, together with a regret upper bound on the algorithm IMED-EC, those quantities will help us control the asymptotic discrepancy between IMED-EC’s regret and the asymptotic lower bound given by Theorem\(1\).

### 3 Information Minimization for bandits with equivalence class

The algorithm we present, IMED-EC, depends on the (weak) indexes introduced in the IMED paper by Honda and Takemura [2015]. At each time step \(t\), for each arm \(a \in \mathcal{A}\), we can compute its IMED index as
\[
I_a(t) = K_F (\hat{\mu}_a(t), \hat{\nu}_a(t)) + \log N_a(t),
\]
where \(\hat{\mu}_a(t) = \max_{a' \in \mathcal{A}} \hat{\mu}_a(t)\) and for each arm \(a \in \mathcal{A}\), \(\hat{\mu}_a(t)\) is the empirical mean of arm \(a\) computed with samples from this arm collected up to time \(t\), \(\hat{\mu}_a(t) = \frac{1}{N_a(t)} \sum_{s=1}^t X_s 1 \{a_s = a\}\), where \(X_s\) is the sample collected by the algorithm at time step \(s\). Let \(\nu \in B_q\) be a bandit configuration having the \(q\)-equivalence property. We denote by \(\mathcal{A}_q(t) = \arg\max_{a \in \mathcal{A}} \{\hat{\mu}_a(t)\}\) the set of empirical optimal arms at time \(t\). We will denote by \(\mathcal{A}_q(t)\) the set of arms having the \(q\) smallest IMED indexes (breaking ties randomly so that this set has size \(q\)). We will also consider the two following quantities for each time \(t\):
\[
I^\ast(t) = \min_{a \in \mathcal{A}_q(t)} I_a(t) = \min_{a \in \mathcal{A}_q(t)} \log N_a(t),
\]
\[
I(t) = \min_{\mathcal{A}' \subseteq \mathcal{A}} \sum_{|\mathcal{A}'| = q} \min_{a' \in \mathcal{A}'} I_a(t) = \sum_{a' \in \mathcal{A}_q(t)} I_a(t).
\]

\(I(t)\) can be computed efficiently by summing the \(q\) smallest elements of the list of IMED indexes. Finding the \(q\) smallest elements can be done by maintaining a sorted array of IMED indexes while computing them. The procedure costs a constant factor of \(\log |\mathcal{A}|\). Computing \(I(t)\) therefore costs \(Ω(|\mathcal{A}| \log |\mathcal{A}|)\), which is only \(\log |\mathcal{A}|\) times larger than looking for the minimal IMED index. Computing \(|\mathcal{A}_q(t)|\) can be done by maintaining a set of arms having the best empirical mean (adds a constant factor). The IMED-EC algorithm is presented in Algorithm\(1\).
While the original problem involves combinatorial quantities, those are not involved in the IMED-EC algorithm. From a time complexity viewpoint, this makes this algorithm on par with other popular algorithms such as UCB, KLUCB, and IMED algorithm. On the contrary, the general structure algorithm OSSB involves solving a combinatorial optimization problem at each time step, which makes it numerically inefficient. We are not aware of any general relaxation method for this algorithm that we could compare IMED-EC with. It is interesting to note that in the case where \( q = 1 \), the IMED-EC algorithms coincide with the OSSB algorithm.

### Intuition

For an arm \( a \), \( N_a(t)K_F(\hat{\mu}_a(t)\|\mu^*) \) may be interpreted as the opposite of a log-likelihood of optimality of that arm. \( \log N_a(t) \) is linked to the log-frequency of play of that arm, the frequency of play of an arm being interpreted as the probability of pulling that arm is a sequence of length \( t \). The IMED algorithm thus can be intuitively understood as an algorithm matching an empirical log-probability with a log-frequency of play. In our setting, there is at least \( q \) elements in each group. It therefore makes sense to test for the optimality of a group rather than single elements. Since all arms are independent, it makes sense to sum the log-likelihood of optimality on all the \( q \)-partitions of the set of arms. Since we have the intuition that this first part is the logarithm of a product of probability, we may compare it to the product of the frequencies. Therefore, we get that important quantities are the sum of IMED indexes for each \( q \) partition of the arms, seen as a comparison between the optimality of this group of \( q \) elements and the associated frequency of play of that group. The minimal IMED index is the one whose frequency of play is the lowest compared to its likelihood of optimality, similarly for the sum of IMED indexes. Other intuitions regarding the fairness (frequency of pulls within the same class) of the algorithm are given in appendix D.

### 4 Regret analysis

In this section, we now detail the main bound on the regret of IMED-EC.

**Theorem 2** (Upper bound on the number of pulls). Under the IMED-EC algorithms, under assumption 1 and 2, the number of pulls of a suboptimal arm \( a \) is upper bounded by:

\[
E_\nu (N_a(T)) \leq \frac{\log T}{qK_F(\nu_a\|\mu_a)} (1 + \alpha(\varepsilon)) + f(\varepsilon),
\]

where \( 0 < \varepsilon < \frac{1}{4} \min_{a \in A\setminus A_*} (\mu_* - \mu_a) \), \( f \) is function that depends on concentration properties on \( F \), and \( \alpha \) tends to 0 as \( \varepsilon \) tends to 0.

**Remark:** \( \alpha \) and \( f \) functions are mostly used for deriving theoretical guarantees in IMED-EC regret analysis. \( \alpha \) is controlled thanks to property 2 as in the paper of Honda and Takemura [2015] for IMED regret analysis. A finite sample analysis can be derived from a careful analysis of the term \( f \). Being more precise requires scrutinizing the properties of the considered family.

**Corollary 1.** Under the IMED-EC algorithms, under assumptions 1 and 2, the number of pulls of a suboptimal arm \( a \) is upper bounded by:

\[
\min_{c_q \subseteq c_a} \sum_{a \in c_q} E_\nu (N_a(T)) K_F(\nu_a\|\mu_a) \leq (1 + \alpha(\varepsilon)) \log T + g(\varepsilon).
\]

where \( 0 < \varepsilon < \frac{1}{4} \min_{a \in A\setminus A_*} (\mu_* - \mu_a) \alpha \) and \( \alpha \) tends to 0 as \( \varepsilon \) tends to 0.

---

**Algorithm 1 IMED-EC (IMED for Equivalent Classes)**

```
Pull each arm once
for t = |A|...T - 1 do
  if I\(^\ast\)(t) ≤ I(t) then
    Pull \( a_{t+1} = \arg\min_{a \in A_*} N_a(t) \) (chosen arbitrarily)
  else
    Pull \( a_{t+1} = \arg\min_{a \notin A_*} I_a(t) \) (chosen arbitrarily)
  end if
end for
```
Theorem 3 (Asymptotic upper bound on the number of pulls). Under the IMED-EC algorithms, under assumption 1 and 2, the number of pulls of a suboptimal arm \( a \) is asymptotically upper bounded by:

\[
\liminf_{t \to +\infty} \frac{\mathbb{E}_\nu(N_a(T))}{\log T} \leq \frac{1}{qK_F(\nu_a\|\mu_*)}.
\]

Discussion This upper bound shows that in particular, the number of pulls of a suboptimal class, \( \sum_{a \in c} \mathbb{E}_\nu(N_a(T)) \) is asymptotically no more than \( \frac{|c|}{qK_F(\nu_a\|\mu_*)}\log T \). This hence matches the lower bound in the non-combinatorial regime. In the combinatorial regime, along with equation (6), this regret upper bound shows that

\[
\frac{|c|}{qK_F(\nu_a\|\mu_*)} \geq \liminf_{t \to \infty} \frac{1}{2} \sum_{a \in c} \mathbb{E}_\nu(N_a(T)) \geq \frac{1}{qK_F(\nu_a\|\mu_*)},
\]

proving that the regret of the proposed IMED-EC does not differ from the optimal lower bound by a factor more than 2. This is a striking result. Equation (6) can be used to have an even more precise control on the discrepancy to the optimal regret bound, as it shows the factor 2 can be actually replaced with \( 1 + \frac{|c|}{q} \min_{a \in c} K_F(\nu_a\|\mu_*) \). Since the factor \( \frac{|c|}{q} \min_{a \in c} K_F(\nu_a\|\mu_*) \) is strictly between 0 and 1 in the combinatorial regime that we are studying, the discrepancy between the lower bound and the regret of IMED-EC indeed is always bounded by 2. On the other hand, this refined error measurement is problem dependant while the factor of 2 is universal.

We provide the full proof of Theorem 3 and Theorem 2 in appendix C, where we also discuss how to weaken assumption 2 and still get the result of theorem 2.

5 Experiments

In this section, we support our theoretical analysis by conducting three sets of experiments. The Python code used to perform those experiments is available on Github. We support our empirical evidences using plots of cumulative regrets. In this section, all the experiments are conducted using gaussian distributions whose means are between 0 and 1 and of unit standard deviation. Those graphs are representative of all the experiments that we conducted and more plots and experiments may be found in the appendix D.

Balanced class, perfect knowledge In this set of experiments, see Figure 1 we focus on the bandit configurations in which all equivalence classes have the same cardinality and assume that we know the number of elements per class. This setting is interesting for two reasons. First, one can compute the theoretical lowerbound without solving a combinatorial optimization problem. Second, the theoretical analysis shows that IMED-EC is asymptotically optimal in this case. This setting will thus allow us to numerically grasp what happens in the most structured case. We compare IMED-EC to unspecialized bandit algorithm, UCB, IMED and KLUCB. To make the comparison fairer we also compare IMED-EC to OSSB, an algorithm specialized in structured bandit. Since OSSB has to solve a combinatorial optimization problem at each time step, we cannot carry experiments on large sets of arms while comparing IMED-EC to it. In this particular setting, we see that while OSSB and IMED-EC are provably asymptotically optimal, IMED-EC numerically performs better in finite time horizon. We recall that it is furthermore numerically more efficient since it does not involve any combinatorial optimization. Without too much surprises, IMED-EC also outperforms unspecialized algorithm.

Imperfect knowledge In the experiment plotted Figure 2 we leverage the knowledge hypothesis and assume that we only know a lower bound on the number of elements per class while the classes are still balanced. We compare IMED-EC to unspecialized bandit algorithm, IMED and KLUCB. We drop OSSB from our test bed due to the computational burden of solving a combinatorial optimization problem at each time step. We can see that the finite time cumulative regret of IMED-EC indeed is much smaller than the regret of the unspecialized algorithms.

Influence of the parameter \( q \) Here we show the numerical robustness of IMED-EC with respect to the lower bound parameter \( q \) on the number of elements per classes. On the same bandit problem,\(^2\) https://github.com/fabienpesquerel/stochastic-bandits-with-groups-of-similar-arms-neurips-2021
Figure 1: 3 classes, 3 distributions per class - set of means = \{0.3, 0.5, 0.9\}

Figure 2: 7 classes, 8 distributions per class - set of means = \{0.1, 0.3, 0.4, 0.5, 0.6, 0.75, 0.9\}

we compare different instances of IMED-EC where different values of $q$ are used. In the legend, *opt.* stands for optimal and corresponds to the largest valid lower bound on the number of elements per class, i.e. the minimal number of elements in a class. The experiment Figure 3 is performed on a bandit problem with 7 classes and an uneven number of distributions per class. The smallest class has 4 elements and the largest 23. While $q$ increases up to the minimum cardinality of a class, we see that the performances of IMED-EC increases. It is rather remarkable that once we go beyond that theoretical threshold, the performances of IMED-EC do not deteriorate. We even found it difficult to find settings to deteriorate them at all. While the expected regret does not seem to deteriorate, we sometimes see that the tails of the regret widen as it can be seen on the plot Figure 3 for $q = 7$ and $q = 20$ since the 0.9 quantile curves are so large for those values of $q$. We interpret part of this robustness to the fact that the relaxation induced in IMED-EC makes the algorithm over explore compared to what the true lower bound suggests. Increasing $q$ reduces the exploration and therefore may improve the performances of the algorithm. However, this robustness is observed even in the case where the classes are balanced. This interpretation thus does not explain everything about the numerical robustness of IMED-EC. This type of experiment does not take more than roughly 10 to 15 minutes on a notebook run in Google Colab depending on the number of arms, the horizon and the number of runs. This supports the numerical efficiency of the relaxation made in IMED-EC.
6 Conclusion

In this paper, we introduced IMED–EC, a numerically efficient algorithm to solve a structured bandit problem for which we derived a lower bound involving a combinatorial optimization problem. While not being asymptotically optimal, we proved that the asymptotic regret of IMED–EC is always smaller than the unstructured one and that we can control the discrepancy with respect to the structured regret lower bound by a factor of at most 2.

Acknowledgments and Disclosure of Funding

This work has been supported by the French Ministry of Higher Education and Research, Inria, Scool, the French Agence Nationale de la Recherche (ANR) under grant ANR-16-CE40-0002 (the BADASS project) the MEL and the I-Site ULNE regarding project R-PILOTE-19-004-APPREN. A Notations and Assumptions

In this section, we first recall a few notations. Then, we provide details about the assumptions made about the distributions. In particular, we make precise the assumption about exponential families we consider, and we also provide an alternative set of assumptions under which our analysis hold. Indeed, our proof techniques naturally apply to the setup considered for the analysis of the IMED strategy. We formalize the corresponding assumptions below in (Assumption 1, 3).

Notations: Given a bandit configuration $\nu$ and an arm $a \in A$, $\hat{\mu}_a(T) = \frac{1}{N_a(T)} \sum_{t=1}^T X_t \mathbb{1}\{a_t = a\}$ where $N_a(T) \sum_{t=1}^T \mathbb{1}\{a_t = a\}$ and $X_t$ is the reward obtained at time $t$. We will denote by $\hat{\mu}_a^n$ the empirical mean of arm $a$ obtained from $n$ i.i.d. samples (and $n$ is not a random variable).

Assumption 1: The family $F$ is such that for all $\kappa \in F$, $\mu \mapsto K_{eq} (\kappa || \mu)$ and $\mu \mapsto K_{eq} (\kappa || \mu)$ are continuous, where $K_{eq}(\kappa || \mu) = \inf_{G \in F} \{ KL(\kappa || G) : E[G](X) = \mu \}$ with KL being a notation for the relative entropy or Kullback-Leibler divergence.

This property is also assumed in Honda and Takemura [2015]. This is especially relevant as they consider reward distributions having a semi-bounded support.

Assumption 2: The family $F$ is an exponential family of dimension 1, i.e. admits the canonical decomposition with respect to some measure

$$p_\theta (x) = \exp \{ t(x) \theta - \psi (\theta) + k(x) \},$$

where $\theta \in \Theta \subseteq \mathbb{R}$ is a parameter, $k$ a real function, $t$ is called the sufficient statistics and $\psi$, the log-partition function, is assumed to be twice differentiable. We assume that $\Theta$ is open and non-empty. We further assume that on $\Theta$, the second derivative, $\psi''$, of the log-partition function is bounded. Formally, there exists $M_{\psi, \Theta}$ such that:

$$\sup_{\theta \in \Theta} \psi'' (\theta) \leq M_{\psi, \Theta}. \quad (10)$$

If $p_\theta$ and $p_{\theta'}$ are two distributions in $F$, then:

$$KL (p_\theta || p_{\theta'}) = \psi (\theta) - \psi (\theta') - (\theta - \theta') \psi' (\theta').$$

Because $F$ is an exponential family of dimension 1, $\psi'' > 0$ and $\psi'$ is strictly increasing. This implies that there is a continuous bijection between the parameter space $\Theta$ and the space of expected values that can be taken between distributions in $F$. Specifically, $\mu : \Theta \mapsto E_{X \sim p_\theta} (X)$ is a bijection on its co-domain, $\mu (\Theta)$. Therefore the KL divergences can be parameterized by the mean and we may write the KL as a function of the means, $\forall \kappa, \chi \in F$, $KL (\kappa || \chi) = d (E_{X \sim \kappa} (X) || E_{X \sim \chi} (X))$.

Therefore, under assumption 2 $K_{eq}$ identifies with the KL and assumption 1 holds by twice differentiability of $\psi$ since it implies the continuity of $\psi$ and $\psi'$. Note that exponential families of dimension 1 have been considered in several other works, see e.g. Korda et al. [2013], Cappé et al. [2013], or Maillard [2018] and Lai [1988] where restriction on $\psi''$ is also considered.

Assumption 3: The family $F$ is the set of distributions with semi-bounded rewards, i.e. whose supports lies in $(-\infty, 1]$. Furthermore, the moment generating function $E (\exp (\lambda X))$ of any distribution $X \in F$ exists in a neighborhood of $\lambda = 0$. For technical reasons linked to the moment generating function, we also assume that the maximal expected rewards of the distributions in $F$ is strictly smaller than 1. Those assumptions on $F$ are the same than the one of the paper Honda and Takemura [2015].

Under assumption 2, the moment generating function can be written as a function of $\psi$,

$$E_{X \sim p_\theta} (\exp (\lambda X)) = \exp (\psi (\theta + \lambda) - \psi (\theta)),\]$$

which is well defined as long as $\theta + \lambda \in \Theta$. This is the reason assumption 1 consider $\Theta$ to be open since in this case, $\theta$ can never be too close to the boundary, i.e. there always exists $\lambda$ small enough such that $\theta + \lambda \in \Theta$, and the moment generating function always exists in a neighborhood of 0.
Remark: The regret lower bound can be proved under assumption 2 or alternatively under assumption 1 and 3. Most of the distributions studied in the bandit literature fall under one of those sets of assumptions. Assumption 2 includes for instance Gaussian bandits (known variance) and Bernoulli distributions. For Bernoulli distributions, the set of considered means should be of the form $(\varepsilon, 1 - \delta)$ with $0 < \varepsilon < 1 - \delta < 1$ in order to upper bound the second derivative of the log-partition function. This situation is represented in Figure 4. Now for Gaussian distributions with known variance, (10) holds trivially.

![Figure 4: Plot of $x \mapsto \text{kl}(\mu \parallel x) = x \log \frac{x}{\mu} + (1 - x) \frac{1-x}{1-\mu}$ (Bernoulli)](image)

Property 1 (Monotonicity of the KL). Under assumption 2, if we assume that,

$$a \leq \mu + \varepsilon < \mu^* - \varepsilon \leq b,$$

then,

$$d(a \parallel b) \geq d(\mu + \varepsilon \parallel \mu^* - \varepsilon).$$

The paper of Honda and Takemura [2015] features a similar property for the $\mathcal{K}_F$ under assumption 1 and assumption 3.

Property 2 (Upper approximation of the KL). Let $\varepsilon$ be such that $\mu + \varepsilon < x - \varepsilon$. Under assumption 2, there exists $\alpha$ such that

$$\frac{1}{d(\mu + \varepsilon \parallel x - \varepsilon)} \leq \frac{1}{d(\mu \parallel x)} (1 + \alpha(\varepsilon)), \quad \text{(11)}$$

with $\alpha(\varepsilon) \to 0$ as $\varepsilon \to 0$.

The paper of Honda and Takemura [2015] features a similar property for the $\mathcal{K}_F$ under assumption 1 and assumption 3.

Proposition 1. Let $\mathcal{F}$ be an exponential family $\mathcal{F}$ of dimension 1 satisfying the hypothesis of assumption 2. Let $X \sim p_{\theta_0} \in \mathcal{F}$ be a real random variable. Denote by $\theta_*$ its true natural parameter and $\hat{\theta}_n$ its empirical parameter computed with $n$ i.i.d. samples from the distribution of $X$. Let $\psi$ be the log-partition function of the family $\mathcal{F}$. Let $\theta$ be the parameter corresponding to the distribution of $\mathcal{F}$ with mean $\mu < \mu^*$ and $\theta_*$ be the parameter corresponding to the distribution of $\mathcal{F}$ with mean $\mu^*$, then

$$\mathbb{P}\left(\text{KL}(p_{\hat{\theta}_n} \parallel p_{\theta_0}) \geq u, \hat{\theta}_n \leq \mu\right) \leq \mathbb{P}\left(\text{KL}(p_{\hat{\theta}_n} \parallel p_{\theta_*}) \geq u + \alpha_\psi(\theta_*, \theta) \sqrt{u}\right) \leq \exp\left(-n \left(u + \alpha_\psi(\theta_*, \theta) \sqrt{u}\right)\right),$$

where $\alpha_\psi(\theta_*, \theta) > 0$.

Proof. For distributions in an exponential family, the Kullback-Leibler divergence can be written using $\psi''$, and therefore:

$$\text{KL}(p_{\hat{\theta}_n} \parallel p_{\theta_0}) = \frac{1}{2} \left(\hat{\theta}_n - \theta\right)^2 \psi'' \left(\gamma \hat{\theta}_n + (1 - \gamma) \theta\right) \geq u.$$
Without loss of generality, we can assume that

Without loss of generality, we can assume that

\[ |\theta - \hat{\theta}_n| \geq \sqrt{\frac{2u}{M}}. \]

because the following derivation will feature the term \( (\theta - \hat{\theta}_n | \psi' (\theta_s) - \psi' (\theta)) \). This term is always positive because \( \bar{\mu}_n \leq \mu < \mu_s \) and \( \mu : \theta \mapsto \mathbb{E}_{X \sim p_0} (X) \) is a continuous bijection. Therefore it has to be strictly monotonous. Since \( \psi' \) is strictly increasing (because \( \psi \) is strictly convex), it preserves the order. Therefore, \( \theta - \hat{\theta}_n \) and \( \psi' (\theta_s) - \psi' (\theta) \) have the same sign.

Since \( \text{KL}(p_0 || p_{\theta'}) = \psi (\theta) - \psi (\theta) - (\theta - \theta') \psi' (\theta') \), we can derive the following sequence of implications:

\[
\Leftrightarrow \text{KL} \left( p_{\hat{\theta}_n} || p_0 \right) \geq u \\
\Leftrightarrow \text{KL} \left( p_{\hat{\theta}_n} || p_0 \right) + \text{KL} \left( p_{\hat{\theta}_n} || p_{\theta_s} \right) \geq u + \text{KL} \left( p_{\hat{\theta}_n} || p_{\theta_s} \right) \\
\Leftrightarrow \text{KL} \left( p_{\hat{\theta}_n} || p_{\theta_s} \right) \geq u + \text{KL} \left( p_{\hat{\theta}_n} || p_{\theta_s} \right) - \text{KL} \left( p_{\hat{\theta}_n} || p_0 \right) \\
\Leftrightarrow \text{KL} \left( p_{\hat{\theta}_n} || p_{\theta_s} \right) \geq u + \text{KL} \left( p_{\theta_s} || p_{\theta_s} \right) + (\theta - \hat{\theta}_n) \left[ \psi' (\theta_s) - \psi' (\theta) \right) \\
\Leftrightarrow \text{KL} \left( p_{\hat{\theta}_n} || p_{\theta_s} \right) \geq u + \text{KL} \left( p_{\theta_s} || p_{\theta_s} \right) + (\theta - \hat{\theta}_n) |g(\theta_s, \theta)| \\
\geq \sqrt{\frac{2u}{M}} \text{ by } (2) \\
\Rightarrow \text{KL} \left( p_{\hat{\theta}_n} || p_{\theta_s} \right) \geq u + \text{KL} \left( p_{\theta_s} || p_{\theta_s} \right) + \left( \sqrt{\frac{2u}{M}} |g(\theta_s, \theta)| \right) \\
\Rightarrow \text{KL} \left( p_{\hat{\theta}_n} || p_{\theta_s} \right) \geq u + \alpha \psi (\theta_s, \theta) \sqrt{u}. \]

The upper bound on the probability is a classical result about exponential families.

\[ \square \]

### B Proof of the regret lower bound

In this section we prove Theorem[1] that we remind below.

**Theorem (Asymptotic lower bound).** Let \( q \in \mathbb{N}_+ \) be a positive integer and \( \nu \in \mathcal{B}_q \) be a bandit configuration having the q-equivalence property. Let \( c \subseteq A \) be a suboptimal equivalence class in \( \nu \).

Assuming uniform consistency, for all suboptimal arm \( a \),

\[
\forall \alpha > 0, \lim_{T \to +\infty} \mathbb{E} \left( \frac{N_a(T)}{T^\alpha} \right) = 0,
\]

assuming assumption 1, we have the following asymptotic bandit dependent lower bound on the number of pulls of arms in \( c \):

\[
\liminf_{T \to +\infty} \inf_{\mu' \in \mathcal{B}_q(\nu_0, c, \chi)} \sum_{a \in c} \mathbb{E}_{\nu_a} (N_a(T)) K_{q} (\nu_a || \mu_s) + \min_{\mu' \in \mathcal{B}_q(\nu_0, c, \chi)} \inf_{\alpha \in \mathbb{C}_q} \sum_{a \in c} \mathbb{E}_{\nu_a} (N_a(T)) K_{q} (\nu_a || \mu'_a) \geq 1,
\]

where \( c_q \) is any subset of \( c \) having \( q \) distinct arms within it.

The proof is standard and makes use of the notion of most confusing instance specialized for this structure in the main part of this paper.
Proof of Theorem 1

Let \( I_T = \{a_k, X_{a_k}\}_{1 \leq k \leq T} \) denote the history of actions and rewards taken by a sequential decision maker algorithm up to time \( T \). Then, using the data processing inequality, it is proved in Garivier et al. [2016] that

\[
\sum_{a \in A} \mathbb{E}_\nu (N_a(T)) \text{KL} (\nu_a || \nu'_a) \geq \text{kl} (\mathbb{E}_\nu (Z) \| \mathbb{E}_{\nu'} (Z)),
\]

for \( Z \in (0, 1) \) a \( \sigma(I_T) \)-measurable random variable and \( \text{kl} \) the Kullback-Leibler divergence between Bernoulli distributions. Let \( c \) be suboptimal class and \( c_q \subseteq c \) be subset of \( q \) elements in \( c \). Applying the previous inequality for \( Z = N_c(T)/T \), for all \( \lambda > \mu_* \) and \( \nu' \in B_q(\nu, c_q, \lambda) \) we have that:

\[
\sum_{a \in c_q} \mathbb{E}_\nu (N_a(T)) \text{KL} (\nu_a || \nu'_a) = \sum_{a \in c_q} \mathbb{E}_\nu (N_a(T)) \text{KL} (\nu_a || \nu'_a) + \sum_{a \not\in c_q} \mathbb{E}_\nu (N_a(T)) \text{KL} (\nu_a || \nu'_a)
\]

\[
\geq \text{kl} \left( \mathbb{E}_\nu \left( \frac{N_a(T)}{T} \right) || \mathbb{E}_{\nu'} \left( \frac{N_a(T)}{T} \right) \right)
\]

\[
\geq \left( 1 - \mathbb{E}_\nu \left( \frac{N_c(T)}{T} \right) \right) \log \frac{1}{1 - \mathbb{E}_{\nu'} \left( \frac{N_c(T)}{T} \right)} - \log 2
\]

\[
= \left( 1 - \mathbb{E}_\nu \left( \frac{N_c(T)}{T} \right) \right) \log \frac{T}{T - \mathbb{E}_{\nu'} (N_c(T))} - \log 2.
\]

Since all arms that are not in \( c \) are suboptimal for \( \nu' \), the uniform consistency hypothesis implies that

\[
\forall 0 < \alpha \leq 1, \quad 0 \leq T - \mathbb{E}_{\nu'} (N_c(T)) = o(T^\alpha);
\]

and therefore, \( T - \mathbb{E}_{\nu'} (N_c(T)) \leq T^\alpha \) for \( T \) large enough. We deduce that, for all \( 0 < \alpha \leq 1 \),

\[
\liminf_{T \to +\infty} \frac{1}{\log T} \log \frac{T}{T - \mathbb{E}_{\nu'} (N_c(T))} \geq \liminf_{T \to +\infty} \frac{1}{\log T} \log \frac{T}{T^\alpha} = 1 - \alpha.
\]

Since all arms within the class \( c \) are suboptimal for \( \nu \) and the considered strategy is assumed to satisfy the uniform consistency hypothesis, \( \mathbb{E}_\nu \left( \frac{N_c(T)}{T} \right) \to 0 \) as \( T \to +\infty \). Together, and letting \( \alpha \) be arbitrarily close to 0, these facts implies that

\[
\liminf_{T \to \infty} \frac{\sum_{a \in c_q} \mathbb{E}_\nu (N_a(t)) \text{KL} (\nu_a || \nu'_a) + \sum_{a \not\in c_q} \mathbb{E}_\nu (N_a(t)) \text{KL} (\nu_a || \nu'_a)}{\log T} \geq 1.
\]

For each \( c_q \), we can minimize this quantity over all confusing instances \( \nu' \in B_q(\nu, c_q, \lambda) \) (with a 0 lower bound if the set is empty), and use the continuity of the KL (assumption 1) to let \( \lambda > \mu_* \) tends toward \( \mu_* \),

\[
\liminf_{T \to \infty} \frac{\sum_{a \in c_q} \mathbb{E}_\nu (N_a(T)) K_F (\nu_a || \mu_*) + \inf_{\mu' \in B_q(\mu, c_q, \lambda)} \sum_{a \not\in c_q} \mathbb{E}_\nu (N_a(T)) K_{cq} (\nu_a || \mu'_a)}{\log T} \geq 1,
\]

where each KL can be minimized independently once \( \mu' \in B_q(\mu, c_q, \lambda) \) has been set, owing to the considered structure. Since this lower bound is valid for all \( c_q \in c \) suboptimal, it is valid for the minimal quantity over all \( q \) partitions,

\[
\liminf_{T \to \infty} \frac{\min_{c_q \subseteq c} \sum_{a \in c_q} \mathbb{E}_\nu (N_a(T)) K_F (\nu_a || \mu_*) + \inf_{\mu' \in B_q(\mu, c_q, \lambda)} \sum_{a \not\in c_q} \mathbb{E}_\nu (N_a(T)) K_{cq} (\nu_a || \mu'_a)}{\log T} \geq 1,
\]

which proves the Theorem [1] \( \square \).
C Proof of the regret upper bound

In this section, we prove the regret upper bound, Theorem\[2\] incurred by the IMED-EC algorithm.

**Theorem** (Upper bound on the number of pulls). Under the IMED-EC algorithms, under assumption 1 and 2, the number of pulls of a suboptimal arm \(a\) is upper bounded by:

\[
\mathbb{E}_\omega \left( N_a(T) \right) \leq \frac{\log T}{q \mathcal{K}_F(\nu_a || \mu_a)} \left( 1 + \alpha(\varepsilon) \right) + f(\varepsilon), \tag{13}
\]

where \(0 < \varepsilon < \frac{1}{3} \min_{a \in \mathcal{A} \setminus \mathcal{A}_*} (\mu_* - \mu_a) \alpha \) and \(\alpha\) tends to 0 as \(\varepsilon\) tends to 0.

The proof proceeds in several steps. We first derive empirical bounds on the number of pulls of a suboptimal arm given that this arm is being pulled at time \(t\).

**Lemma 4** (Empirical bounds). Let \(a_{t+1}\) be the pulled arm at time \(t+1\), and \(a\) be any arm belonging to \(\mathcal{A}_*(t)\) at some time \(t\). Under the IMED-EC algorithm, if \(a_{t+1} \in \mathcal{A}_*(t)\),

\[
N_{a_{t+1}}(t) \leq N_a(t), \tag{14}
\]

\[
\log \left( N_{a_{t+1}}(t) \right) \leq \min_{c_q \leq c_r} \sum_{k \in c_q} N_k(t) d(\hat{\mu}_k(t) || \hat{\mu}_r) + \log N_k(t), \tag{15}
\]

and if \(a_{t+1} \notin \mathcal{A}_*(t)\),

\[
q N_{a_{t+1}}(t) d(\hat{\mu}_{a_{t+1}} || \hat{\mu}_r) \leq \log t, \tag{16}
\]

\[
q \log \left( N_{a_{t+1}}(t) \right) \leq \min_{c_q \leq c_r} \sum_{k \in c_q} N_k(t) d(\hat{\mu}_k(t) || \hat{\mu}_r) + \log N_k(t). \tag{17}
\]

**Proof.** Assume that the chosen arm, \(a_{t+1}\), belongs to \(\mathcal{A}_*(t)\), then by definition of \(I(t)\) and \(I^*(t)\),

\(I^*(t) \leq I(t)\). \(I^*(t) = I_{a_{t+1}}\) because \(a_{t+1}\) is the chosen arm amongst elements of \(\mathcal{A}_*(t)\), hence belongs to \(\arg \min_{a \in \mathcal{A}_*(t)} \log N_a(t)\). Equation (14) follows and \(N_{a_{t+1}} \leq N_a(t)\) for all \(a \in \mathcal{A}_*(t)\). Equation (15) then follows from the fact that:

\[
\log N_{a_{t+1}}(t) = I^*(t)
\]

\[
\leq I(t)
\]

\[
= \min_{|\mathcal{A}'| = q} \sum_{a' \in \mathcal{A}'} I_{a'}(t)
\]

\[
\leq \min_{c_q \leq c_r} \sum_{k \in c_q} N_k(t) d(\hat{\mu}_k(t) || \hat{\mu}_r) + \log N_k(t).
\]

Assume that the chosen arm, \(a_{t+1}\), does not belong to \(\mathcal{A}_*(t)\). Then \(I(t) \leq I^*(t)\). The flow of control of the IMED-EC algorithm implies that \(a_{t+1}\) is an arm with minimal IMED index. By definition of \(I(t)\), \(q\) times \(I_{a_{t+1}}\) will always be smaller than or equal to \(I(t)\):

\[
q \left( N_{a_{t+1}}(t) d(\hat{\mu}_{a_{t+1}}(t) || \hat{\mu}_r(t)) + \log N_{a_{t+1}}(t) \right) \leq I(t). \tag{18}
\]

By definition of \(I^*(t)\), there exists \(a \in \mathcal{A}_*(t)\) such that \(I^*(t) = \log N_a(t)\) implying that \(I^*(t) \leq \log t\). Since \(I(t) \leq I^*(t)\), it implies that \(I(t) \leq \log t\). From equation (18) we deduce equation (16).

\[
q N_{a_{t+1}}(t) d(\hat{\mu}_{a_{t+1}} || \hat{\mu}_r) \leq \log t.
\]

Last, equation (17) can be deduced from the definition of \(I(t)\) and equation (18):

\[
q \log N_{a_{t+1}}(t) \leq q \left( N_{a_{t+1}}(t) d(\hat{\mu}_{a_{t+1}}(t) || \hat{\mu}_r(t)) + \log N_{a_{t+1}}(t) \right)
\]

\[
\leq I(t)
\]

\[
= \min_{|\mathcal{A}'| = q} \sum_{a' \in \mathcal{A}'} I_{a'}(t)
\]

\[
\leq \min_{c_q \leq c_r} \sum_{k \in c_q} N_k(t) d(\hat{\mu}_k(t) || \hat{\mu}_r) + \log N_k(t).
\]
If we were to substitute empirical means with real ones, so that \( \hat{\mu}_a(t) = \mu_a \) for all \( a \in \mathcal{A} \) and \( \mathcal{A}_i(t) = \mathcal{A}_i \), then one can see that equation (16) gives us the desired behavior, i.e. if \( a_{t+1} \) is a suboptimal arm, \( N_{a_{t+1}}(t) \leq \frac{\log t}{q \mu_{a_{t+1}} \mu_+} \). For distributions having concentration around the mean property we will be able to say that, for large enough \( t \), with high probability, for all arms \( a \in \mathcal{A} \), \( |\hat{\mu}_a(t) - \mu_a| \leq \varepsilon \). In this case, we shall still have a desired property. This is the statement of the next Lemma. We then proceed to show the concentration properties later on.

**Lemma 5.** Let \( 0 < \varepsilon \leq \frac{1}{3} \min_{a \in \mathcal{A}} (\mu_+ - \mu_a) \). Assume that \( a_{t+1} \) is the pulled arm at time \( t+1 \) and \( a_{t+1} \in \mathcal{A} \setminus \mathcal{A}_i \) is a suboptimal arm. Let’s assume that \( \hat{\mu}_{a_{t+1}}(t) \leq \mu_a + \varepsilon \). Let’s also assume that \( \hat{\mu}^*(t) \geq \mu_* - \varepsilon \). Those hypothesis can be read as:

\[
\hat{\mu}_{a_{t+1}}(t) \leq \mu_{a_{t+1}} + \varepsilon < \mu_* - \varepsilon \leq \mu^*(t).
\]  

Lemma 4 and the monotonicity of the KL divergence implied by assumption 2, imply that:

\[
N_{a_{t+1}}(t) \leq \frac{\log t}{q \mu_{a_{t+1}} \mu_*} (1 + \alpha_a(\varepsilon)),
\]

with \( \alpha_a(\varepsilon) \to 0 \) as \( \varepsilon \to 0 \).

**Proof.** Equation (19) is a direct consequence of the hypothesis of the Lemma. The strict inequality, \( \mu_{a_{t+1}} < \mu_* \), implies that \( a_{t+1} \) cannot belong to \( \mathcal{A}_i(t) \). Hence, equation (16) from Lemma 4 applies and

\[ qN_{a_{t+1}}(t)d(\mu_{a_{t+1}} || \mu^*) \leq \log t. \]

Because \( \hat{\mu}_{a_{t+1}}(t) < \mu_* - \varepsilon \leq \hat{\mu}^*(t) \), using assumption 2 that implies \( d(\hat{\mu}_{a_{t+1}} || \mu_* - \varepsilon) \leq d(\hat{\mu}_{a_{t+1}} || \hat{\mu}^*(t)) \), we have that:

\[ qN_{a_{t+1}}(t)d(\mu_{a_{t+1}} || \mu_* - \varepsilon) \leq \log t. \]

Similarly, \( \hat{\mu}_{a_{t+1}}(t) \leq \mu_{a_{t+1}}(t) + \varepsilon < \mu_* - \varepsilon \) and using assumption 2 again, \( d(\mu_a + \varepsilon || \mu_* - \varepsilon) \leq d(\hat{\mu}_{a_{t+1}} || \mu_* - \varepsilon) \), we proved equation (20):

\[
N_{a_{t+1}}(t) \leq \frac{\log t}{q \mu_{a_{t+1}} + \varepsilon \mu_* - \varepsilon}.
\]

Using equation (11) from property 2 we deduce that there exists \( \alpha_a \) as in property 2, such that:

\[
N_{a_{t+1}}(t) \leq \frac{\log t}{q \mu_{a_{t+1}} \mu_*} (1 + \alpha_a(\varepsilon)).
\]

\( \square \)

In order to better clarify the proof of Theorem 2, we add two more lemmas that help emphasize where the hypothesis regarding the distribution space \( \mathcal{F} \) are used. The first one is about decomposing the event of choosing a suboptimal arm.

**Intuition about Lemma 6** The intuition of the next lemma is the following. Let \( a \) be a suboptimal arm. We will decompose the event of choosing arm \( a \) at time \( t+1 \), \( \{a_{t+1} = a\} \), on three events. We recall that \( \hat{\mu}^*(t) = \max_{a \in \mathcal{A}} \hat{\mu}_a(t) \). Let \( \varepsilon \) be such that \( 0 < \varepsilon \leq \frac{1}{3} \min_{a \in \mathcal{A}_i} (\mu_+ - \mu_a) \) as in Lemma 5.

From Lemma 5, we know that under the event \( \{\hat{\mu}^*(t) \geq \mu_* - \varepsilon, \hat{\mu}_{a_{t+1}} \leq \mu_{a_{t+1}} + \varepsilon\} \), the number \( N_{a_{t+1}} \) is upper bounded by the desired asymptotic term. The intuition of this term is given in section 3 and made formal in Lemma 5. We want to play an arm as frequently as the likelihood of optimality of the group of size \( q \) it may belong to.

Whatever the space of distributions \( \mathcal{F} \), we will always assume a concentration around the mean property. Therefore, we know that the event \( \{\hat{\mu}_{a_{t+1}} \geq \mu_{a_{t+1}} + \varepsilon\} \) can be controlled by concentration...
The remainder of the two aforementioned events, \( \{a_{t+1} \notin \mathcal{A}_*, \hat{\mu}^*(t) < \mu_* - \varepsilon\} \), is the most technical and difficult to handle. An intuition may be the following. If \( \hat{\mu}^*(t) \leq \mu_* - \varepsilon \), then it is true that for any arm \( k \in \mathcal{A}_* \), \( \hat{\mu}_k(t) \leq \mu_* - \varepsilon \). In that case, it means that with a high enough probability, most of the arm \( k \in \mathcal{A}_* \) have not been pulled too much. The IMED and IMED–EC algorithms try to match likelihood of optimality with frequency of play. Therefore, we cannot keep not playing arm in \( \mathcal{A}_* \), (i.e. we cannot play the suboptimal arm for too long before playing \( k \)) and when that happens, we will mostly observe a regression toward the mean making the event even more unlikely. We will rely on concentration tools to make the regression toward the mean statement more precise.

We now formalize those intuitions in Lemma 6.

**Lemma 6 (Fundamental decomposition).** Let \( a \) be a suboptimal arm. Let \( \varepsilon \) be such that \( 0 < \varepsilon \leq \frac{1}{3} \min_{a \notin \mathcal{A}_*} (\mu_* - \mu_a) \) as in Lemma 5. Under IMED–EC, shifting the time index \( t \) by \( \mathcal{A} \) (each arm is pulled once at the beginning), \( N_a(t) = \sum_{t=1}^{T} \mathbb{1} \{a_{t+1} = a\} \), the number of time a suboptimal arm \( a \) has been pulled after time \(|\mathcal{A}|\) can be upper bounded by:

\[
\sum_{t=1}^{T} \mathbb{1} \{a_{t+1} = a\} \leq \sum_{t=1}^{T} \mathbb{1} \left\{ a_{t+1} = a, N_a(t) \leq \frac{\log t}{qd(\mu_a + \varepsilon \| \mu_* - \varepsilon)} \right\} \tag{22}
\]

\[
+ \sum_{t=1}^{T} \mathbb{1} \{a_{t+1} = a, \hat{\mu}^*(t) \geq \mu_* - \varepsilon, \hat{\mu}_a(t) > \mu_a + \varepsilon\} \tag{23}
\]

\[
+ \sum_{t=1}^{T} \mathbb{1} \{a_{t+1} = a, \hat{\mu}^*(t) < \mu_* - \varepsilon\}. \tag{24}
\]

**Proof.** Following the aforementioned intuition, we decompose the event \( \{a_{t+1} = a\} :\)

\[
\{a_{t+1} = a\} = \{a_{t+1} = a, \hat{\mu}^*(t) \geq \mu_* - \varepsilon\} \cup \{a_{t+1} = a, \hat{\mu}^*(t) < \mu_* - \varepsilon\}
\]

\[
= \{a_{t+1} = a, \hat{\mu}^*(t) \geq \mu_* - \varepsilon, \hat{\mu}_a(t) \leq \mu_a + \varepsilon\}
\]

\[
\cup \{a_{t+1} = a, \hat{\mu}^*(t) \geq \mu_* - \varepsilon, \hat{\mu}_a(t) > \mu_a + \varepsilon\}
\]

\[
\cup \{a_{t+1} = a, \hat{\mu}^*(t) < \mu_* - \varepsilon\}
\]

Using Lemma 5.

Using indicators of those events and shifting the time index \( t \) by \( \mathcal{A} \) (each arm is pulled once at the beginning), we can upper bound \( N_a(t) = \sum_{t=1}^{T} \mathbb{1} \{a_{t+1} = a\} \), the number of time a suboptimal arm \( a \) as been pulled after time \(|\mathcal{A}|\):

\[
\sum_{t=1}^{T} \mathbb{1} \{a_{t+1} = a\} \leq \sum_{t=1}^{T} \mathbb{1} \left\{ a_{t+1} = a, N_a(t) \leq \frac{\log t}{qd(\mu_a + \varepsilon \| \mu_* - \varepsilon)} \right\} \tag{22}
\]

\[
+ \sum_{t=1}^{T} \mathbb{1} \{a_{t+1} = a, \hat{\mu}^*(t) \geq \mu_* - \varepsilon, \hat{\mu}_a(t) > \mu_a + \varepsilon\} \tag{23}
\]

\[
+ \sum_{t=1}^{T} \mathbb{1} \{a_{t+1} = a, \hat{\mu}^*(t) < \mu_* - \varepsilon\}. \tag{24}
\]

The second lemma is about bounding equation (24) by a quantity that can be controlled in both assumptions 2 and 3. This particular control is very specific to the \( q \)-equivalence structure and rely heavily on the fact that there is at least \( q \) distributions in the optimal class \( \mathcal{A}_* \).
Lemma 7 (q-factorization). Let \( a \) be a suboptimal arm and \( c \subseteq A_\ast \) be any subset of \( q \) optimal arms. Then, under the IMED-EC algorithm,

\[
\sum_{t=1}^{T} \mathbb{1} \left\{ a_{t+1} = a, \hat{\mu}^\ast (t) < \mu_\ast - \varepsilon \right\} \leq \prod_{k \in c} \sum_{m_k \geq 1} \mathbb{1} \left\{ \hat{\mu}_k^{m_k} < \mu_\ast - \varepsilon \right\} m_k \exp \left( m_k d (\hat{\mu}_k^{m_k} \| \mu_\ast - \varepsilon) \right).
\]

Proof. We want to control part (24) of the upper bound on the number of pulls of a suboptimal arm \( a \). From Lemma 4, equation (15) and equation (17), we know that \( \log (N_{a_{t+1}} (t)) \leq \min_{c_\ast \subseteq c_\ast} \sum_{k \in c_\ast} N_k (t) d (\hat{\mu}_k (t) \| \hat{\mu}^\ast) + \log N_k (t) \). Let \( c \subseteq A_\ast \) be any subset of \( q \) optimal arms.

Since we are studying the event \( \{ a_{t+1} = a \} \) this inequality becomes

\[
\log (N_a (t)) \leq \min_{c_\ast \subseteq c_\ast} \sum_{k \in c_\ast} N_k (t) d (\hat{\mu}_k (t) \| \hat{\mu}^\ast) + \log N_k (t)
\]

\[
\leq \sum_{k \in c} N_k (t) d (\hat{\mu}_k (t) \| \hat{\mu}^\ast) + \log N_k (t).
\]

We use this inequality to control the sum (24).

\[
(24) = \sum_{t=1}^{T} \mathbb{1} \left\{ a_{t+1} = a, \hat{\mu}^\ast (t) < \mu_\ast - \varepsilon \right\}
\]

\[
= \sum_{t=1}^{T} \left\{ \hat{\mu}^\ast (t) < \mu_\ast - \varepsilon, \log (n) \leq \sum_{k \in c} N_k (t) d (\hat{\mu}_k (t) \| \hat{\mu}^\ast (t)) + \log N_k (t) \right\} \times \mathbb{1} \left\{ a_{t+1} = a \right\}
\]

\[
= \sum_{t=1}^{T} \sum_{n=1}^{T} \mathbb{1} \left\{ \hat{\mu}^\ast (t) < \mu_\ast - \varepsilon, \log (n) \leq \sum_{k \in c} N_k (t) d (\hat{\mu}_k (t) \| \hat{\mu}^\ast (t)) + \log N_k (t) \right\} \times \mathbb{1} \left\{ a_{t+1} = a, N_a (t) = n \right\}.
\]

Since \( \hat{\mu}^\ast (t) < \mu_\ast - \varepsilon \) and \( \hat{\mu}^\ast (t) = \max_{b \in A} \hat{\mu}_b (t) \), we can use the monotonicity of the KL divergence to state that for all \( k \in c \), \( d (\hat{\mu}_k^{m_k} \| \hat{\mu}^\ast (t)) \leq d (\hat{\mu}_k (t) \| \mu_\ast - \varepsilon) \). This implies the inclusion of events,

\[
\left\{ \hat{\mu}^\ast (t) < \mu_\ast - \varepsilon, \log (n) \leq \sum_{k \in c} N_k (t) d (\hat{\mu}_k (t) \| \hat{\mu}^\ast (t)) + \log N_k (t) \right\} \subseteq
\]

\[
\left\{ \hat{\mu}^\ast (t) < \mu_\ast - \varepsilon, \log (n) \leq \sum_{k \in c} N_k (t) d (\hat{\mu}_k (t) \| \mu_\ast - \varepsilon) + \log N_k (t) \right\},
\]

which can be used to control the indicators. Furthermore, \( \hat{\mu}^\ast (t) \leq \mu_\ast - \varepsilon \) implies that \( \max_{k \in c} \hat{\mu}_k (t) \leq \mu_\ast - \varepsilon \) since \( \max_{k \in c} \hat{\mu}_k (t) \leq \max_{k \in A} \hat{\mu}_k (t) \). Therefore,

\[
\left\{ \hat{\mu}^\ast (t) < \mu_\ast - \varepsilon, \log (n) \leq \sum_{k \in c} N_k (t) d (\hat{\mu}_k (t) \| \hat{\mu}^\ast (t)) + \log N_k (t) \right\} \subseteq
\]

\[
\left\{ \max_{k \in c} \hat{\mu}_k (t) < \mu_\ast - \varepsilon, \log (n) \leq \sum_{k \in c} N_k (t) d (\hat{\mu}_k (t) \| \mu_\ast - \varepsilon) + \log N_k (t) \right\},
\]
which we use to control the indicators. We then obtain

\[ [24] \leq \sum_{t=1}^{T} \sum_{n=1}^{T} \left\{ \max_{k \in c} \mu_k^m < \mu_* - \varepsilon, \log (n) \leq \sum_{k \in c} N_k(t) d(\hat{\mu}_k(t) \parallel \mu_* - \varepsilon) + \log N_k(t) \right\} \times \\
\left\{ a_{t+1} = a, N_a(t) = n \right\} \\
= \sum_{m_1 \geq 1} \sum_{n \geq 1} \sum_{t=1}^{T} \left\{ \max_{k \in c} \mu_k^m < \mu_* - \varepsilon, \log (n) \leq \sum_{k \in c} m_k d(\hat{\mu}_k^m \parallel \mu_* - \varepsilon) + \log m_k \right\} \times \\
\left\{ a_{t+1} = a, N_a(t) = n \right\} \prod_{k \in c} \left\{ N_k(t) = m_k \right\} \leq 1 \\
\leq \sum_{m_1 \geq 1} \sum_{n \geq 1} \sum_{t=1}^{T} \left\{ \max_{k \in c} \mu_k^m < \mu_* - \varepsilon, \log (n) \leq \sum_{k \in c} m_k d(\hat{\mu}_k^m \parallel \mu_* - \varepsilon) + \log m_k \right\} \times \\
\left\{ a_{t+1} = a, N_a(t) = n \right\} \prod_{k \in c} \left\{ N_k(t) = m_k \right\} \leq 1 \\
= \sum_{m_1 \geq 1} \sum_{n \geq 1} \left\{ \max_{k \in c} \mu_k^m < \mu_* - \varepsilon, \log (n) \leq \sum_{k \in c} m_k d(\hat{\mu}_k^m \parallel \mu_* - \varepsilon) + \log m_k \right\} \times \\
\sum_{t=1}^{T} \left\{ a_{t+1} = a, N_a(t) = n \right\} \leq 1 \\
\leq \sum_{m_1 \geq 1} \sum_{n \geq 1} \left\{ \max_{k \in c} \mu_k^m < \mu_* - \varepsilon, \log (n) \leq \sum_{k \in c} m_k d(\hat{\mu}_k^m \parallel \mu_* - \varepsilon) + \log m_k \right\} .
\]

We can then factorize the following term

\[ \left\{ \max_{k \in c} \mu_k^m < \mu_* - \varepsilon, \log (n) \leq \sum_{k \in c} m_k d(\hat{\mu}_k^m \parallel \mu_* - \varepsilon) + \log m_k \right\} = \\
\left\{ \max_{k \in c} \mu_k^m < \mu_* - \varepsilon \right\} \left\{ \log (n) \leq \sum_{k \in c} m_k d(\hat{\mu}_k^m \parallel \mu_* - \varepsilon) + \log m_k \right\} ,
\]
We are now ready to prove the Theorem 2.

Assumption 2 and assumption 3 are two possible assumptions that make it possible to control the Equation (25).

\[
\sum_{m \geq 1} \prod_{k \in c} \left\{ \max_{k \in c} \hat{\mu}_k^m < \mu_* - \varepsilon \right\} m_k \exp \left( m_k d \left( \hat{\mu}_k^m \| \mu_* - \varepsilon \right) \right)
\]

Since \( \exp \left( \sum_{k \in c} m_k d \left( \hat{\mu}_k^m \| \mu_* - \varepsilon \right) \right) = \prod_{k \in c} m_k \exp \left( m_k d \left( \hat{\mu}_k^m \| \mu_* - \varepsilon \right) \right) \) and

\[
\sum_{m \geq 1} \prod_{k \in c} \left\{ \max_{k \in c} \hat{\mu}_k^m < \mu_* - \varepsilon \right\} m_k \exp \left( m_k d \left( \hat{\mu}_k^m \| \mu_* - \varepsilon \right) \right)
\]

which is linked to the upper bound one can have on \( \mathbb{P} \left( d \left( \hat{\mu}_k^m \| \mu_* - \varepsilon \right) > u, \hat{\mu}_k^m \leq \mu_* - \varepsilon \right) \) and whether or not it is better than \( \exp \left( -m_n u \right) \). As we can see, controlling this terms amounts to a concentration hypothesis of the distributions in \( F \). Assumption 2 and assumption 3 are two possible assumptions that make it possible to control the Equation (25).

We are now ready to prove the Theorem 2.

Proof of Theorem 2 Let \( \alpha \) be a suboptimal arm and let \( \varepsilon \) be such that \( 0 < \varepsilon \leq \frac{1}{3} \min_{\alpha \notin A_*} \left( \mu_* - \mu_\alpha \right) \).

By Lemma 1 we have the following decomposition:

\[
\sum_{t=1}^{T} \prod_{k \in c} \left\{ \max_{k \in c} \hat{\mu}_k^m < \mu_* - \varepsilon \right\} m_k \exp \left( m_k d \left( \hat{\mu}_k^m \| \mu_* - \varepsilon \right) \right)
\]
Control of equation (22)  Equation (22) can be controlled as a random variable without any concentration tools. The following derivation bound the sum (22) by:

\[
(22) = \sum_{t=1}^{T} \mathbb{I} \left\{ a_{t+1} = a, N_a(t) \leq \frac{\log t}{qd (\mu_a + \epsilon \| \mu_s - \epsilon )} \right\}
\]

\[
= \sum_{n=1}^{T} \sum_{t=1}^{T} \mathbb{I} \left\{ n \leq \frac{\log t}{qd (\mu_a + \epsilon \| \mu_s - \epsilon )} \right\} \mathbb{I} \left\{ a_{t+1} = a, N_a(t) = n \right\}
\]

\[
= \sum_{n=1}^{T} \mathbb{I} \left\{ n \leq \frac{\log T}{qd (\mu_a + \epsilon \| \mu_s - \epsilon )} \right\} \sum_{t=1}^{T} \mathbb{I} \left\{ a_{t+1} = a, N_a(t) = n \right\} \leq 1
\]

\[
\leq \sum_{n=1}^{T} \mathbb{I} \left\{ n \leq \frac{\log T}{qd (\mu_a + \epsilon \| \mu_s - \epsilon )} \right\}
\]

\[
= \left[ \log T \right] \left[ \frac{\log T}{qd (\mu_a + \epsilon \| \mu_s - \epsilon )} \right]
\]

\[
\leq \frac{\log T}{qd (\mu_a + \epsilon \| \mu_s - \epsilon )}.
\]

The derivation relies on the simple fact that an indicator function is upper bounded by 1. This part proved that:

\[
\sum_{t=1}^{T} \mathbb{I} \{ a_{t+1} = a \} \leq \frac{\log T}{qd (\mu_a + \epsilon \| \mu_s - \epsilon )}
\]  \hfill (22)

\[
+ \sum_{t=1}^{T} \mathbb{I} \{ a_{t+1} = a, \hat{\mu}^*(t) \geq \mu_s - \epsilon, \hat{\mu}_a(t) > \mu_a + \epsilon \}
\]  \hfill (23)

\[
+ \sum_{t=1}^{T} \mathbb{I} \{ a_{t+1} = a, \hat{\mu}^*(t) < \mu_s - \epsilon \}
\]  \hfill (24)

Control of equation (23)  Equation (23) can be controlled using large deviation hypothesis on the set of distributions that are considered. It should be noted that this term is also bounded by \( O(1) \) in the paper Honda and Takemura [2015]. Therefore, this term can be also be handled under assumption 3. We give an upper bound under assumption 2. The common fact of those two assumptions is the \textit{light-tail} property of the considered distributions. A distributions is said \textit{light-tailed} if its moment generating function exists in a neighborhood of 0. In that case one can apply a concentration property.
since Cramér’s theorem applies (see [Dembo and Zeitouni, 1998, Theorem 2.2.3]).

\[
\sum_{t=1}^{T} \mathbb{1}\{a_{t+1} = a, \hat{\mu}_t(t) \geq \mu_* - \varepsilon, \hat{\mu}_a(t) > \mu_a + \varepsilon\} \\
\leq \sum_{t=1}^{T} \mathbb{1}\{a_{t+1} = a, \hat{\mu}_a(t) > \mu_a + \varepsilon\} \\
= \sum_{n=1}^{T} \sum_{t=1}^{T} \mathbb{1}\{a_{t+1} = a, N_a(t) = n, \hat{\mu}_a(t) > \mu_a + \varepsilon\} \\
= \sum_{n=1}^{T} \sum_{t=1}^{T} \mathbb{1}\{\hat{\mu}_a^n > \mu_a + \varepsilon\} \sum_{t=1}^{T} \mathbb{1}\{a_{t+1} = a, N_a(t) = n\} \\
\leq \sum_{n=1}^{T} \mathbb{1}\{\hat{\mu}_a^n > \mu_a + \varepsilon\}.
\]

Taking the expectation of both sides,

\[
\mathbb{E}(23) \leq \sum_{n=1}^{T} \mathbb{P}(\hat{\mu}_a^n > \mu_a + \varepsilon)
\]

which is a series of positive real numbers between 0 and 1 if we set \(T = +\infty\). The reason we are interested in the limit is because we want \(\mathbb{E}(\text{23})\) to be upper bounded by a time independent quantity. For this series to be convergent, we need the terms of the series, \(\mathbb{P}(\hat{\mu}_a(n) > \mu_a + \varepsilon)\), to converge fast enough toward 0. Denoting \(\varphi_a\) the moment generating function of arm \(a\) and \(\psi_a = \log \varphi_a\) the cumulant generating function we derive that for all \(\lambda > 0\):

\[
\mathbb{P}(\hat{\mu}_a^n > \mu_a + \varepsilon) = \mathbb{P}\left(\sum_{i=1}^{n} X_i^a > n (\mu_a + \varepsilon)\right) \\
\leq \frac{\varphi_a(\lambda)^n}{e^{n\lambda(\mu_a+\varepsilon)}} \text{ Markov inequality} \\
= \exp\left(n (\psi_a(\lambda) - \lambda (\mu_a + \varepsilon))\right) \\
= \exp\left(-n (\lambda (\mu_a + \varepsilon) - \psi_a (\lambda))\right).
\]

Since this inequality is true for all \(\lambda\) we can minimize the right-hand side expression which features the Legendre-Fenchel transformation of \(\psi_a\) (also known as the Cramer transform). We denote \(\psi^*_a(\varepsilon) = \sup_\lambda (\lambda (\mu_a + \varepsilon) - \psi_a (\lambda))\) the Legendre-Fenchel transform of \(\psi_a\) that exists thanks to assumption 2.

For distributions in \(F\) this quantity is strictly positive as it is proved in [Dembo and Zeitouni, 1998]. Therefore, we proved that

\[
\mathbb{P}(\hat{\mu}_a^n > \mu_a + \varepsilon) \leq \exp\left(-n \psi^*_a(\varepsilon)\right) \\
= \left(\exp\left(-\psi^*_a(\varepsilon)\right)\right)^n,
\]
with $0 \leq \exp\left(\psi_a^* (\varepsilon)\right) < 1$. This result is enough to bound equation (23) in expectation,

$$E(23) \leq \sum_{n=1}^T P(\hat{\mu}_n > \mu_a + \varepsilon)$$

$$\leq \sum_{n=1}^{+\infty} P(\hat{\mu}_n > \mu_a + \varepsilon)$$

$$\leq \sum_{n=1}^{+\infty} \exp (-n \psi_a^* (\varepsilon))$$

$$= C_a (\varepsilon),$$

where $C_a (\varepsilon)$ denotes the limit of the series $\sum_{n=1}^{+\infty} \exp (-n \psi_a^* (\varepsilon))$. This part and the previous one proved that

$$E\left(\sum_{t=1}^T \mathbb{1} \{a_{t+1} = a, \hat{\mu}_a (t) < \mu_a - \varepsilon\}\right) \leq \log T \frac{\log T}{q d (\mu_a + \varepsilon \| \mu_a - \varepsilon)}$$

$$+ C_a (\varepsilon)$$

$$+ E\left(\sum_{t=1}^T \mathbb{1} \{a_{t+1} = a, \hat{\mu}_a (t) < \mu_a - \varepsilon\}\right).$$

**Control of equation (24)** We are left to control part (24) of the upper bound on the number of pulls of a suboptimal arm. Let $c \subseteq A_*$ be any subset of $q$ optimal arms. From the q-factorization lemma, Lemma 7, we know that

$$E\left(\sum_{t=1}^T \mathbb{1} \{a_{t+1} = a, \hat{\mu}_a (t) < \mu_a - \varepsilon\}\right) \leq \prod_{k \in c} \sum_{m_k \geq 1} \mathbb{1} \{\hat{\mu}_a^m < \mu_a - \varepsilon\} m_k \exp (m_k \theta_k \| \mu_a - \varepsilon\)).$$

Since samples from the different arms are independents, the inequality holds in expectation:

$$E(24) \leq \prod_{k \in c} E\left(\sum_{m_k \geq 1} \mathbb{1} \{\hat{\mu}_a^m < \mu_a - \varepsilon\} m_k \exp (m_k \theta_k \| \mu_a - \varepsilon\)).$$

The proof of Lemma 14 in [Honda and Takemura 2015], from equation (26), features a very similar quantity. In particular, it has been proved that for all $k \in c$, under the assumption 3

$$E\left(\sum_{m_k \geq 1} \mathbb{1} \{\hat{\mu}_a^m < \mu_a - \varepsilon\} m_k \exp (m_k \theta_k \| \mu_a - \varepsilon\)). \leq D_{IMED} (\varepsilon),$$

where $D_{IMED} (\varepsilon)$ is given by equation (28) of [Honda and Takemura 2015]. The proof of Lemma 14 in [Honda and Takemura 2015] relies on the Proposition 11 of [Honda and Takemura 2015]. Under assumption 2, Proposition 1 allows us to upper bound the left hand side of Equation (27) by a time independent quantity using the same strategy of integration by parts used in [Honda and Takemura 2015]:

$$E\left(\sum_{m_k \geq 1} \mathbb{1} \{\hat{\mu}_a^m < \mu_a - \varepsilon\} m_k \exp (m_k \theta_k \| \mu_a - \varepsilon\)). \leq D (\varepsilon).$$
All combined, those derivations proved that

\[ Pr(\text{Theorem } 3) \]

Theorem 2 we just proved states that because \( \epsilon \) is a set of size \( q \), we get that for all \( \epsilon > 0 \), we can deduce a bound on equation (24).

which proves our claim. Therefore, under assumption 2 or assumption 3, we can deduce a bound on equation (24).

\[ \text{All combined, those derivations proved that} \]

\[ \mathbb{E}(\sum_{t=1}^{T} \mathbb{1}_{a_{t+1} = a}) \leq \frac{\log T}{qd(\mu_{a} + \epsilon \| \mu_{a} - \epsilon \|)} + C_{a}(\epsilon) + D(\epsilon)^{q} \]

and can be written as

\[ \mathbb{E}(N_{a}(t)) \leq \frac{\log T}{qd(\mu_{a} + \epsilon \| \mu_{a} - \epsilon \|)} + C_{a}(\epsilon) + D(\epsilon)^{q}. \]

Using property 2 for the KL divergence, we finally get the final expression proving the Theorem 2.

\[ \mathbb{E}(N_{a}(t)) \leq \frac{\log T}{qd(\mu_{a} \| \mu_{a})} (1 + \alpha_{a}(\epsilon)) + f(\epsilon), \]

with \( f(\epsilon) = C_{a}(\epsilon) + D(\epsilon)^{q} \).

**Proof of Theorem 2** Theorem 2 we just proved states that

\[ \mathbb{E}(N_{a}(t)) \leq \frac{\log T}{qd(\mu_{a} \| \mu_{a})} (1 + \alpha_{a}(\epsilon)) + f(\epsilon) \]

with \( f(\epsilon) = C_{a}(\epsilon) + D(\epsilon)^{q} \). Dividing both sides by \( \log T \), we get that for all \( \epsilon \) small enough

\[ \lim_{t \rightarrow +\infty} \frac{\mathbb{E}_{\epsilon}(N_{a}(T))}{\log T} \leq \frac{1}{qd(\mu_{a} \| \mu_{a})} (1 + \alpha_{a}(\epsilon)). \]

Letting \( \epsilon \) tends to 0 proves the Theorem 3.
D Experiments

In this section, we illustrate the performances of IMED-EC with a few more plots and explore the dispatching of this algorithm. By dispatching, we mean to compare the discrepancy in the number of pulls within a class. In particular, we are interested in the behavior of the different sampling strategies within the optimal class. The different settings are the same as the one presented in the main part of this paper. We present additional details.

Balanced class, perfect knowledge In this set of experiments, see Figure 5, we focus on the bandit configurations in which all equivalence classes have the same cardinality and assume that we know the number of elements per class. Recall that since OSSB has to solve a combinatorial optimization problem at each time step, we cannot carry experiments on large set of arms while comparing IMED-EC to it. In this particular setting, we see that while OSSB and IMED-EC are provably asymptotically optimal, IMED-EC numerically performs better in finite time horizon.

Next, we explore the dispatching of IMED-EC and compare it to the one of KLUCB and IMED. We run the three algorithms 1000 times on a bandit problem whose number of class is 4 with means \{0.1, 0.3, 0.6, 0.9\} and 10 Gaussian distributions with unit variance within each class. The chosen horizon is 2000. We assume that IMED-EC has perfect knowledge on the number of elements per class, 10. In the next section, similar plots (see Figure 11, Figure 12, Figure 13, and Figure 14) can be found where IMED-EC only knows a strict lower bound on the number of elements per class. For each of the 4 classes, we report the histogram accounting for the number of times distributions within each class has been pulled. Specifically, we are interested in the statistical order of the number of pulls within each class. After each run, for each class, we sort the number of pulls. The histograms are built using those sorted number of pulls. Error bars corresponds to the standard deviations and have been clipped to not go below the x-axis.

For the most suboptimal class, Figure 6, not much can be said since the number of pulls is very low. Still, one can see that the progression of the order statistics for KLUCB and IMED is somewhat linear while it seems more exponential for IMED-EC. (Note that we use these terms here informally.)

The same linear versus exponential apparent behavior can be seen on Figure 7.

On Figure 8, one can clearly a difference in the behaviour of KLUCB and IMED, that have small error bars, and IMED-EC that have a large error bar for the most pulled arm within the least suboptimal class. We can clearly see how risky it might be to reduce the exploration from this error bar. However, this risk is compensated by the fact that there is at least $q$ similar distributions. This can be read from the fact that the sum of all the number of pulls within this class for KLUCB and IMED is above 200 which is roughly the maximal number of pulls of IMED-EC within this class computed using the upper bounds (given by the maximal value of the standard deviation).
Finally, Figure 9 enables to compare the behaviours of the algorithms within the optimal class. It seems clear that, at least numerically, IMED-EC is not a fair algorithm in finite time (in the sense that it does not equally distribute the pulls between arms from the same class) and that it leverages the lower bound on the number of elements per class to play a more risky strategy, and benefits from it. Again, we observe the linear versus exponential progression in the order statistics of the number of pulls.
Figure 9: 4 classes, 10 distributions per class - set of means = \{0.1, 0.3, 0.6, 0.9\} - class of mean 0.9

**Imperfect knowledge**  In the experiment plotted Figure 10, we leverage the knowledge hypothesis and assume that we only know a lower bound on the number of elements per class while the classes are still balanced. We compare IMED-EC to unspecialized bandit algorithm, IMED and KLUCB. We can see that the finite time cumulative regret of IMED-EC indeed is much smaller than the regret of the unspecialized algorithms, showing the ability of IMED-EC to effectively exploit this weak knowledge.

For the sake of completeness, we explore the dispatching of IMED-EC and compare it to the one of KLUCB and IMED on this setting. We run the three algorithms 1000 times on an bandit problem whose number of class is 4 with means \{0.1, 0.3, 0.6, 0.9\} and 10 Gaussian distributions with unit variance within each class. The chosen horizon is 2000. We assume that IMED-EC does not have perfect knowledge on the number of elements per class, and we use 3 as the lower bound parameter of IMED-EC. For each of the 4 classes, we report the histogram accounting for the number of times distributions within each class has been pulled. Error bars corresponds to the standard deviations and have been clipped to not go below the \(x\)-axis.

Comments that were respectively made for Figure 6, Figure 7, Figure 8, and Figure 9 can similarly made for Figure 11, Figure 12, Figure 13, and Figure 14.

Interestingly, we can tell apart the two settings by looking at the behaviour of the algorithms for the least suboptimal class, *i.e.* comparing Figure 8 and Figure 13. In Figure 8, the error bar for the most pulled elements is much larger than in Figure 13, meaning that the algorithm at stakes explore less.
Figure 11: 4 classes, 10 distributions per class - set of means = \{0.1, 0.3, 0.6, 0.9\} - mean 0.1

Figure 12: 4 classes, 10 distributions per class - set of means = \{0.1, 0.3, 0.6, 0.9\} - mean 0.3

Figure 13: 4 classes, 10 distributions per class - set of means = \{0.1, 0.3, 0.6, 0.9\} - mean 0.6

**Influence of the parameter** $q$  Here we show the numerical robustness of IMED-EC with respect to the lower bound parameter $q$ on the number of elements per classes. On the same bandit problem, we compare different instances of IMED-EC where different values of $q$ are used. In the legend, $opt.$ stands for optimal and corresponds to the largest valid lower bound on the number of elements per class, i.e. the minimal number of elements in a class. The experiments done for Figure 15 are performed on a bandit problem with 4 classes and 10 distributions per class. While $q$ increases up to the minimum cardinality of a class, we see that the performances of IMED-EC increases, which is expected. It is rather remarkable that once we go beyond that theoretical threshold, the performances of IMED-EC do not seem to deteriorate.
Figure 14: 4 classes, 10 distributions per class - set of means = \{0.1, 0.3, 0.6, 0.9\} - mean 0.9

Figure 15: 4 classes, 10 distributions per class - set of means = \{0.1, 0.3, 0.6, 0.9\}

Finally, we explore the *dispatching* of IMED-EC and compare it to the one of KLUCB and IMED on this setting. We run the three algorithms 1000 times on a bandit problem whose number of class is 7 with means \{0.1, 0.3, 0.4, 0.5, 0.6, 0.75, 0.9\} and an uneven number of Gaussian distributions with unit variance within each class. The chosen horizon is 2000. We assume that IMED-EC does not have perfect knowledge on the number of elements per class, and we use 3 as the lower bound parameter of IMED-EC. For some classes, we report the histogram accounting for the number of times distributions within each chosen class has been pulled. Error bars corresponds to the standard deviations and have been clipped to not go below the x-axis.

The comments that can be made about those plots are similar to the one that were already made for similar experiments. We included them to show that the behaviour of IMED-EC (and also the behaviour of IMED and KLUCB) is consistent across multiple settings. In particular, the algorithm IMED-EC exhibits the same aforementioned behaviour for the least suboptimal class, as it can be seen by comparing Figure 18 to the corresponding Figure 8 and Figure 13.
Figure 16: 7 classes - unbalanced - set of means = \{0.1, 0.3, 0.4, 0.5, 0.6, 0.75, 0.9\} - mean 0.3

Figure 17: 7 classes - unbalanced - set of means = \{0.1, 0.3, 0.4, 0.5, 0.6, 0.75, 0.9\} - mean 0.5

Figure 18: 7 classes - unbalanced - set of means = \{0.1, 0.3, 0.4, 0.5, 0.6, 0.75, 0.9\} - mean 0.75

Figure 19: 7 classes - unbalanced - set of means = \{0.1, 0.3, 0.4, 0.5, 0.6, 0.75, 0.9\} - mean 0.9
